Purpose: Accurate detection of clinically significant prostate cancer (PC) and correct risk attribution are essential to individually counsel men with PC. Multiparametric MRI (mpMRI) facilitates correct localization of index lesions within the prostate and MRI-targeted prostate biopsy (TPB) helps to avoid the shortcomings of conventional biopsy such as false-negative results or underdiagnosis of aggressive PC. In this review we summarize the different sequences of mpMRI, characterize the possibilities of incorporating MRI in the biopsy workflow and outline the performance of targeted and systematic cores in significant cancer detection. Furthermore, we outline the potential of MRI in patients undergoing active surveillance (AS) and in the pre-operative setting.

Materials and methods: An electronic MEDLINE/PubMed search up to February 2015 was performed. English language articles were reviewed for inclusion ability and data were extracted, analyzed and summarized.

Results: Targeted biopsies significantly outperform conventional systematic biopsies in the detection of significant PC and are not inferior when compared to transperineal saturation biopsies. MpMRI can detect index lesions in app. 90% of cases as compared to prostatectomy specimen. The diagnostic performance of biparametric MRI (T2w + DWI) is not inferior to mpMRI, offering options to diminish cost- and time-consumption. Since app 10% of significant lesions are still MRI-invisible, systematic cores seem to be necessary. In-bore biopsy and MRI/TRUS-fusion-guided biopsy tend to be superior techniques compared to cognitive fusion. In AS, mpMRI avoids underdetection of significant PC and confirms low-risk disease accurately. In higher-risk disease, pre-surgical MRI can change the clinically-based surgical plan in up to a third of cases.

Conclusions: mpMRI and targeted biopsies are able to detect significant PC accurately and mitigate insignificant PC detection. As long as the negative predictive value (NPV) is still imperfect, systematic cores should not be omitted for optimal staging of disease. The potential to correctly classify aggressiveness of disease in AS patients and to guide and plan prostatectomy is evolving.

Introduction

Prostate cancer (PC) is the most common noncutaneous malignancy in men in Western countries (1). In 2011, around 900,000 new cases and among 250,000 deaths were recorded worldwide (1). According to the European Association of Urology guidelines an elevated prostate specific antigen (PSA)-level should trigger an extended 12-core systematic TRUS-guided biopsy, which is endorsed as the optimal biopsy method (2). This diagnostic strategy is based on random sampling and is largely operator dependent. Consecutively, this biopsy technique is subject to sampling error and provides poor characterization of PC aggressiveness (3). The main shortcomings of the 12-core TRUS biopsy technique are failure to detect clinically significant cancer and imprecise PC risk stratification (undersampling) and detection of small low-risk clinically insignificant cancers (overdetection) (4,5). This diagnostic uncertainty can lead to repeat biopsy, delayed detection of significant disease or disease overtreatment. The need of precise tumor detection and staging increases in the context of recent trends of active surveillance (AS) and focal therapy.

Since its first usage in 1983, magnetic resonance imaging (MRI) is increasingly used for PC diagnosis because of growing availability and multiparametric imaging, combining anatomic and functional data (6). A number of studies confirm the diagnostic reliability of multiparametric MRI (mpMRI) for PC detection (4,7). In the past, widespread acceptance of mpMRI suffered from a lack of standardized diagnostic criteria for reporting of results, leading to a substantial variability in interpretation (8). To standardize the evaluation and reporting of prostate MRI, the European Society of Urogenital Radiology (ESUR) published guidelines based on an expert consensus in 2012, termed the Prostate Imaging Reporting and Data System (PIRADS) (9). This guideline provides explicit and standardized criteria for Likert-scoring of multiparametric sequences [T2w, diffusion-weighted imaging (DWI), dynamic contrast enhanced imaging (DCE) and MR-spectroscopy] (9). Since then, the PIRADS score has been externally validated with a good accuracy, suggesting that this 5-point-Likert scoring allows to detect PC accurately (10-13). The T2w, DWI and DCE sequences have been maturing as being most accurate for PC detection, whereas the use of MR-spectroscopy has mostly been abandoned.

The accuracy of mpMRI and PIRADS scoring has not only been established for biopsy specimen, but also for histopathologic correlation using prostatectomy specimen. In the pre-PIRADS era, Isebaert et al. found a sensitivity of 58.5% for PC detection (14). Recent publications demonstrate detection rates of significant PC between 80-96% for MRI compared to whole-mount sections (15-17).

MRI-targeted biopsies (TB) can be taken by various approaches. Visual estimation (VE) allows the adaptation of TB in clinical practice without costs for new equipment, but lacks real-time feedback regarding accuracy. The effectiveness and accuracy of VE biopsy vary among studies. Haffner et al. detected significant PC in 43% of men using TB and missed only 5.2% of significant PC as compared to standard biopsy (18). In addition, Kasivisvanathan et al. reported non-inferiority of VE TB as compared to transperineal mapping (19). However, the performance of VE TB is strongly experience dependent, limiting the widespread of this approach (3). In-bore MRI guided biopsy is an alternative, offering a cancer detection rate (CDR) of 41% and finding mostly clinically significant PC (20). These results have been corroborated by recent studies, demonstrating that in-bore MRI guided biopsy is a feasible technique, requiring fewer cores to detect similar rates of significant cancer and a median detection rate for all PC around 42% (21,22). However, the use of in-bore TB alone might be critical as several studies demonstrate that app. 10% of significant tumors are MRI-invisible (12,13,23,24).

MRI/TRUS-fusion-guided biopsies with software-registration potentially overcome limitations of cognitive fusion through reproducible methods of identifying MRI lesions on ultrasound (25). The utility of TB versus systematic biopsy (SB) has recently been established in a large cohort that has been analysed according to standards formulated by an international consensus meeting (26,27). Siddiqui et al. published the results of 1,003 patients undergoing MRI-TB of MRI-visible lesions in addition to standard 12-core biopsy (26). In their study, TB detected significantly more (30%, P<0.001) high-risk PC and 17% fewer low-risk PC (P=0.002) compared to SB (26). However, TB alone missed 8.1% of intermediate- and high-risk PC compared to the combination of TB and SB. Moreover, when compared to prostatectomy specimen the negative predictive value of TB to exclude significant disease was still imperfect (70%). Furthermore, when TB were compared to a different reference test (24-core transperineal SB), 20.9% of significant PC were detected by TB alone, whereas 12.8% were missed by TB alone (12). Overall, no statistically significant difference in significant PC detection occurred between both approaches (12). In conclusion, for optimal staging both TB and SB should be taken to detect significant PC accurately, echoing other
Recent publications (12, 24).

MpmMRI also has the potential to predict extracapsular extension (ECE) on radical prostatectomy (RP) (28). Somford et al. and Marcus et al. have demonstrated promising negative (NPV) and positive predictive values (PPVs) of ECE and the possibility of changing the surgical strategy (28, 29).

In this review, we evaluate the role of MRI in the pre-biopsy setting and the utility to predict RP outcome. Moreover, we describe the different MRI sequences and biopsy techniques.

**Materials and methods**

We searched MEDLINE/PubMed for English language manuscripts published up to February 2015 using the following search terms: MRI, multiparametric MRI, biparametric MRI, MRI-guided, MRI-targeted, image-guided, MRI-ultrasound fusion, cognitive, prostate, PC, biopsy, detection, AS, risk assessment, risk stratification, PIRADS, NMR, cancer detection, visual estimation, and extraprostatic extension (EPE). Non-English articles were excluded from analysis. Inclusion criteria were male gender, adult and availability of full text. Overall, 653 publications were included. Data were extracted and analyzed.

The literature search and study pre-selection is graphically displayed in Figure 1.

**Results**

**Limitations of the contemporary systematic biopsy technique**

**False-negative biopsy**

Standard 12-core transrectal biopsies need optimal spatial distribution for tumor detection and are consequently subject to sampling error. Undersampling occurs in up to 30-80% of patients with significant PC (4, 26, 30). Especially cancers with small volume or PC located in the transition zone (TZ) and anterior prostate are difficult to detect by random 12-core transrectal approaches (31, 32). Additionally, larger glands are subject to greater risk of false-negative biopsy (30). To overcome this sampling error, multiple repeat biopsies are often performed. However, these can result in overdetection of indolent cancers that may not have caused harm (3).

**Incorrect risk stratification**

The undersampling of the prostate during systematic transrectal procedures can lead to incorrect risk stratification of PC. More strict definitions of PC do not only include the Gleason score (GS) (≥3+4 or ≥4+3), but also the lesion volume (33, 34). Random biopsies risk inadequate lesion sampling, as the cancer core length is significantly decreased compared to TB (35, 36). This may reveal a small length of tumor in a core with a low GS, when in fact a significant lesion may occur adjacent to the biopsy location (3, 37).
Another risk of conventional TRUS-guided biopsy is upgrading. Dinh et al. recently analyzed a SEER-database cohort of 10,273 patients, and found an upgrading of 44% from clinically low-risk PC in biopsy to GS ≥7 in RP specimen (38). Shaw et al. also found an upgrading of 50.2% from low-risk PC to intermediate- and high-risk PC in RP specimen analyzing 848 patients (39).

Detection of clinically insignificant disease

Approximately 60% of men over age of 80 years harbor clinically insignificant PC without suffering from it at autopsy studies (40). These clinically insignificant PC are often identified by chance during a SB and may contribute to overdetection and overtreatment of indolent PC (5,41,42).

Risk of infection

Although the TRUS-biopsy approach is the standard diagnostic approach for over 20 years, significant side-effects and morbidity are rising, especially post-biopsy infections (43). In a national Swedish cohort of 51,321 men, Lundström et al. showed an infection rate of 6% after transrectal biopsy (44). Prevention and prophylaxis from infections caused by rectal milieus is especially important, since the frequency of Escherichia coli resistant to fluoroquinolone increased from 11% in 2006 to 13% in 2011 (44,45). Additionally, Feliciano et al. described not only a fluoroquinolone resistance of Escherichia coli, but also to gentamicin (22% of cases), trimethoprim/sulfamethoxazole in 44%, piperacillin in 72% and ampicillin in 94% (46). Furthermore Cohen et al. described an initial fluoroquinolone resistance of Escherichia coli in 24.4% of cases in an initial biopsy cohort of 416 men (47).

Transperineal approach

The transperineal approach is an alternative to the transrectal entry path, causing less risk of infection. Additionally, the anterior prostate is easier to access. Furthermore, transperineal mapping biopsy specimen undergo significantly less upgrading on RP specimen (8% versus 52% in a publication of Crawford et al.) (48). One disadvantage is that transperineal biopsies are more painful. Thus, anesthesia is needed, especially in case of saturation or mapping biopsies averting the wide-spread use of this approach.

Extended systematic and saturation biopsies

The debate on the optimal number of biopsy core samples that should be taken is still open. Ploussard et al. have demonstrated that an increase from 12 to 21 cores significantly increases the detection rate of significant PC (49). Transperineal mapping biopsy (TPMB) aims for optimal staging and detection of all significant PC by using an external grid of 5 mm (50,51). Lecornet et al. have shown that TPMB detects nearly all significant PC lesions above 0.5 mL (52). However, TPMB is significantly more invasive than SB leading to urinary retention and the potential for oversampling of clinically insignificant PC, which often results in overtreatment. Valerio et al. report that, beside an accurate index lesion detection, insignificant PC was detected in up to 42.9% of TPMB (53). Additionally, the prostate is mobile, deformable and swells during biopsy, so real-time sampling errors in vivo might still occur (25). Thus, Ukimura et al. conclude that the specific clinical indication for TPMB, remains under debate (25).

Prostate mpMRI for PC detection and localization

The first application of prostate MRI was published by Hricak et al. in 1983 (54). Since then, the field strength of MRI increased from 0.35 Tesla (T) to 3T and standardized multiparametric sequences (T2w, DWI and DCE) were established. MRI and TB detect more clinically significant PC compared to standard 12-core TRUS-biopsy (4,26,37,55). To establish a standardized MRI technique and a quantitative structured reporting system, the ESUR promoted the ESUR guidelines in 2012 (9). In 2015, a revised PIRADS version was published by the American College of Radiologists (56). The imaging techniques are described in the following sections.

T2-weighted imaging

T2w MR images have high spatial resolution and clearly define the prostate’s zonal anatomy (Figure 2) (59). PC in the peripheral zone often appear as a low signal intensity area on T2w (9). The degree of intensity decrease differs with the GS, with higher GS components showing lower signal intensities (60). However, T2w imaging can result in false positive findings, as low-signal intensity also occurs in acute and chronic prostatitis, atrophy, scars, post-irradiation, hyperplasia and post-biopsy hemorrhage (3). Because of the heterogeneous appearance of benign prostate hyperplasia with both, increased and decreased signal intensity, PC in the TZ can be difficult to distinguish from benign tissue (61,62). Morphologic features such as homogeneously low signal intensity, irregular edges of the suspicious lesion, invasion into the urethra or the anterior fibromuscular stroma...
(AFMS), and lenticular shape are helpful for detection of TZ tumors (63). Moreover, the updated PIRADS guidelines state that T2w Imaging is the dominant sequence for the TZ [Table 1 (see part A) and Table 2] (56).

**Diffusion-weighted imaging (DWI)**

DWI is based on Brownian motion and measures random motion of water molecules. The strength of the gradient that determines the degree of diffusion-weighting is reflected by the sequence’s b value. Performing DWI with multiple b values, it is possible to compute the apparent diffusion coefficient (ADC) based on the signal intensity measured at each b value image to quantify the restriction of water diffusion. B values of 0, 100 and 800-1,000 s/mm$^2$ are recommended (9). For ADC calculation, the highest b value should be 1,000 s/mm$^2$ (9). The utility of higher b values up to 2,000 s/mm$^2$ is under debate (64,65). On ADC maps, PC frequently shows low ADC values and an inverse correlation exists between quantitative ADC values and the GS (65-67). While ADC does correlate with GS, the confidence intervals are widely overlapping, limiting the ability to use ADC as a surrogate of GS (3,67).

Limitations of DWI include low signal-to-noise ratio and image distortion, both of which become more problematic at higher b values (3). Nonetheless, DWI is a widely available technique, and given its association with tumor aggressiveness, it may prove to be the primary sequence for tumor detection and characterization, especially in the peripheral zone, were it is recommended as the dominant sequence [Table 1 (see part B) and Table 2] (56,67).

**Dynamic contrast-enhanced imaging and role of biparametric MRI**

Dynamic contrast-enhanced MRI consists of a series of fast T1w-sequences covering the prostate, before and after a bolus injection of gadolinium chelate (9). It is the most common imaging method for evaluation of tumor vascularity (68). As many other malignancies, PC often demonstrate early enhancement compared to normal tissue (69). However, kinetics of PC enhancement can be variable and heterogeneous (56). Recent guidelines recommend to include DCE not to miss some small significant PC (56). If focal lesions are found, T2w and DWI images should be carefully interrogated for corresponding abnormalities (56). At present, the additional value of DCE is discussed controversially. Some publications state that addition of DCE and/or DW imaging to T2-weighted MRI significantly improved sensitivity from 63% to 79-81% in the peripheral zone, while maintaining a stable specificity (7). Yoshizako et al. demonstrated that the combined use of DWI, DCE, and T2-weighted MRI increased the accuracy in detection of TZ cancer compared to T2w alone, from 64% to 79% (70). The PIRADS 2015 guidelines still recommend the use of DCE, whereas Rosenkrantz et al., Hoeks et al., Rais-Bahrami et al. and Schimmoller et al. postulate that additional DCE did not improve the detection and localization accuracy of significant PC in all zones and especially in the TZ (56,62,71-73). When performed, DCE is positive when there is enhancement that is focal, earlier or contemporaneous with enhancement of adjacent normal prostatic tissue and usually corresponding.

Technique of MRI targeted biopsy

In general, TB can be performed as direct in-bore MRI-guided biopsy, as VE biopsy or as fusion-biopsy with software-registration. Fusion-guided biopsies consist of co-registering pre-acquired MRI data with real-time US with the use of software and computing of the probe location and can be performed using elastic fusion systems (e.g., Koelis Urostation, Eigen Artemis) or rigid fusion systems (e.g., Philips Uronav, MedCom BiopSee; Figure 3).

Visual estimation

VE allows adaptation of TB in clinical practice without significant upfront cost, but carries a significant learning curve and lacks real-time feedback regarding accuracy (3,19,74). MRI and TRUS images are superimposed by a cognitive overlay of TRUS and MR images during biopsy, using a printed document or by displaying MR images on the screen of a workstation located in the TRUS room, adjacent to the TRUS platform (19). The physician aims the target lesion with knowledge of lesion localization on MRI. Several publications analyzed the value of cognitively performed TB. Lawrentschuk et al. detected a higher performance of cognitive TB over random cores, in particular in anterior lesions (75). Haffner et al. compared, in a retrospective study, results of TB with those of 12 random biopsies in 555 patients. A TB strategy alone would have necessitated only a mean of 3.8 cores per patient and avoided unnecessary biopsies in 38% of patients with a normal MRI, while avoiding the diagnosis of insignificant cancer detected by random biopsies in 13% cases (18). In this study, 13 significant cancers were missed with TB alone and 12 significant cancers were missed with the standard approach (18). In another study, Puech et al. found that MRI prior to biopsy improved CDR which raised from 59% by 12-core SB to 65% by cognitive TB. With regard to significant cancer (Cancer core length >3 mm on any core and GS >3+3) CDR was 67% for TB and 52% for conventional biopsies (35). Labanaris et al. showed that TB allow an exact match of biopsy and surgical GS in 90% and concluded that MRI should be performed prior to biopsy to solve underestimation of GS by SB (76). Kasivisvanathan et al. detected a statistically not significantly lower CDR of TB (57% cancer detection rate) compared to a strict reference-test of TPMB (62% CDR) (19). Wysock et al. published that VE was slightly inferior to MRI/TRUS-fusion biopsy for all PC (CDR 20.3% vs. 32.0%, P=0.1374) and for significant PC (CDR 15.1% vs. 26.7%) (74). In conclusion, the currently published studies show an improved accuracy and cancer detection compared to conventional TRUS-biopsy.

In-bore MRI-guided biopsy

The in-bore biopsy approach has the advantages of accurate depiction of needle placement, fewer sampled cores, and a low likelihood of missed targets if these are MRI-visible (20). In-bore biopsy is a targeted biopsy directly performed within the MRI tube. It has the disadvantage of increased cost- and time consumption and the inability to routinely sample the remaining gland (20,21). This is in particular important, as MRI misses app. 10% of significant lesions compared to final RP pathology (15,16). Quentin et al. demonstrate an excellent significant cancer detection by in-bore TB of 92.2% (21). In the series of Hoeks et al.
265 patients with suspicious lesions on mpMRI with prior negative TRUS-biopsies underwent transrectal in-bore TB, resulting in a CDR of 41% with 87% of these detected cancers found to be clinically significant (20). Multiple studies have corroborated these results, demonstrating that in-bore MRI-guided biopsy is a feasible diagnostic technique in patients with prior negative biopsy, offering a median detection rate of 42%, significantly higher than reported detection rates for repeat SB (22). Pokorny et al. demonstrated that an MRI-guided biopsy pathway reduced the diagnosis of low-risk PC by 89.4% and increased the detection of intermediate-risk/high-risk PC by 17.7% (36). However, compared to RP specimen, 14.7% of patients were undergraded by the mpMRI and MRI-guided biopsy approach (36).

MRI/TRUS-fusion-guided biopsy

MR-fusion-guided TB are more often histologically informative and, thus, may overcome the limitations of cognitive TB through reproducible methods for identification of MRI lesions on ultrasound (3,74). Several commercial platforms have become available varying in the method of co-registration and utilizing different hardware platforms for aligning the biopsy with the co-registered image (3,77). MRI/TRUS-fusion-guided biopsy potentially has greater reproducibility due to less operator dependence and by providing real time feedback of actual biopsied locations, compared to VE (3). Disadvantages include higher costs for the software/device, dependence on the software for accuracy, and associated learning curve and operator training (3). Recent publications focused on the detection of PC and of significant disease compared to conventional SB or TPMB as reference-test (4,12,15,26,36,37,78,79). Using the Uronav system and conventional 12-core TRUS-biopsy as reference-test, Siddiqui et al. recently demonstrated in a cohort of >1,000 patients that TB diagnosed 30% more high-risk cancers versus standard biopsy (P<0.001) and 17% fewer low-risk cancers (P=0.002) using primary Gleason pattern four as significance level (26). Salami et al. and Rastinehad et al. used GS ≥3+4 as significant cancer and published that 14.3% to 20.9% of significant PC were detected by TB alone and missed by standard TRUS approach (37,78). Moreover, upgrading from insignificant to significant PC by MRI/TRUS-fusion guided biopsy occurred in 23.5% (37). On the other hand, 4/105 significant PC were missed by MRI/TRUS-fusion guided biopsy (37). Kuru et al. and Radtke et al. from our group analyzed the detection accuracy of TB compared to a transperineal saturation biopsy as reference-test (12,79). TB detected significantly more PC than SB on per-core analysis (30% vs. 8.2%) (79). Analyzing the detection rates of TB versus transperineal SB, TB alone did not lead to a significantly lower detection of significant PC, defined as GS ≥3+4 (P=0.711) (12). At the same time, TB alone avoided overdiagnosis of 43.8% of low-grade tumors (12). Only applying TB in man with suspicious MRI (PIRADS score ≥2) may reduce both, cost and over-detection of low-risk PC, but would have underdiagnosed 11 patients with GS ≥3+4 PC (14.6%) (12). Using RP as reference test, Baco et al. demonstrated that 98% of index tumors, defined as the highest GS or biggest volume in case of multifocality with equal GS, were diagnosed by MRI and that the correct location was diagnosed in 98% by MRI/TRUS-fusion guided TB, using the Koelis Urostation (Figure 4) (15). However, in the larger prostatectomy cohort of the Siddiqui publication, the negative predictive value (NPV) of TB to exclude significant disease was only 70%.

Comparative studies of different targeted biopsy approaches

Only a few studies have compared the CDR between different targeting techniques and the results are controversial (3,5,74). In a study comparing VE with two MRI/TRUS-fusion devices, Delongchamps et al. reported that cognitive fusion-biopsy was not significantly better than SB, while both software co-registration devices tested (Esaote/MyLabTMTwice and Koelis/Urostation) significantly increased CDR compared to SB using conditional logistic regression analysis in a cohort of 391 patients (5). Wysock et al. compared MRI/TRUS-fusion-guided biopsies using the Eigen/Artemis system versus VE targeting in a prospective study including 125 men with suspicious lesions (74). They found that MRI/TRUS-fusion-guided biopsies had a slightly improved CDR compared to VE for all cancers (32% vs. 26.7%, P=0.1374) and for GS ≥3+4 (20.3% vs. 15.1%, P=0.0523). Puech et al. observed no difference in the CDR of PC for rigid software co-registration using MedCom Navigator compared to cognitive fusion TB (53% vs. 47%) (35). Additionally, no differences were detected for cancer positivity in the subgroups of posterior (46 of 79, 58%), anterior (33 of 79, 42%), or smallest (25 of 79, 32%) MR imaging targets (35).

Targeted versus systematic SB

Several publications investigated the detection accuracy
of TB and SB alone or in combination (12,26,37,78). As described above, Siddiqui et al. from the National Institutes of Health (NIH) analyzed the value of TB vs. 12-core TRUS-biopsy in a cohort of 1003 men (26). Additional standard biopsy diagnosed 22% more PC, but 83% of these cases were low-risk PC, while only 5% were high-risk PC (26). The number needed to biopsy with SB in addition to TB to detect one high-risk PC was 200 men (26). Rastinehad et al. detected an upgrading from insignificant to significant PC by MRI/TRUS-fusion guided biopsy versus SB in 23.5% (37). On the other hand, only 3.8% of significant PC (defined as GS ≥3+4) were missed by MRI/TRUS-fusion guided biopsy (37). Le et al. reported that 17% were diagnosed with GS ≥3+4 PC by 12-core random biopsy alone, whereas 36% of GS ≥3+4 PC were exclusively detected by TB (24).

When MRI/TRUS-fusion guided biopsies are compared to transperineal saturation biopsies, exclusive detection by fusion-guided biopsy occurred in 20.9% of GS ≥3+4 PC and on the other hand in 12.8% by SB alone (12). Valerio et al. published in a systematic review of 14 publications, that MRI/TRUS-fusion biopsies detected a median of 9.1% additional clinically significant cancers (range, 5-16.2%) that were missed by standard biopsy alone (53). In contrast, standard biopsies detected a median of 2.1% (range, 0-12.4%) additional clinically significant cancers that were missed by MRI/TRUS-fusion biopsies (53). If the standard biopsy is only a TRUS-biopsy approach, the range of significant PC diagnosed exclusively by standard biopsy stood at 0-7% (53). In conclusion, Le et al. and Radtke et al. postulated that the combination of TB and SB represents the reference-standard for cancer detection (12,24). As long as TB miss 3.8-17% of significant PC (according to different definitions of significance), SB should not generally be omitted. Men with suspicion of PC should be counseled and then they may choose if they prefer reduction of overdiagnosis (TB alone) or maximum safety (combination of TB and SB) (12).

**Correlation of MRI with surgical pathology**

The utility of mpMRI to accurately detect PC and index lesions within the prostate is supported by several studies (15,80-82). An example from our group is given in Figure 4. The correlation between histologic lesions and MRI findings is difficult to determine, especially due to the variations between MR sections and prostatectomy slices, and the shrinkage during histopathologic processing of the specimens (80). Correction for this variability has been attempted by using a shrinkage factor, as well as different methods of co-registration between histology and imaging (82-85). However, the tissue shrinkage factor varies among different studies between 1.14 and 1.50 (83). Rosenkrantz et al. published one of the first series comparing whole mount sections to mpMRI in 51 patients. They detected a sensitivity and a PPV for an exact match between suspicious lesion on MRI and whole-mount section (belonging to the same region in a 18-sector scheme) in 60.2% and 65.3% of
patients, respectively (81). Regarding approximate matches (discrepancy of up to one region) sensitivity was 75.9% and PPV was 82.6% (81). Turkhey et al. published a sensitivity of 80% for the detection of significant PC using T2w Imaging and a sensitivity of 94% for significant lesions in the PZ (82,86). Rud et al. used a biparametric MRI (T2w and DWI) to detect the index lesion on consecutive RP, defined as the tumor with EPE, or highest GS, or the largest tumor volume (TV), in that order of priority, in 199 patients (80). In their study, 92% of index lesions and 70% of all lesions were correctly identified by MRI (80). In lesions with TV above 0.5 mL, 86% of cancers were correctly assessed (80). Only 8% of index lesions and 14% of lesions >0.5 mL were missed by MRI (80). In the PIRADS era, Baco et al. analyzed the accuracy of mpMRI and MRI/TRUS-fusion guided biopsy in 135 consecutive patients (15). The location of the index lesion was correctly defined in 95% of patients (15). In the remaining 5%, the index tumor was invisible on MRI, but each had a small TV ≤0.4 mL (15). For the MRI-visible index lesions, targeted biopsy-proven PC showed 100% correspondence with the location of the index lesion in RP specimens (15,56,87). The combination of SB and TB detected the index tumor location correctly in 132/135 (98%) of patients (15). Interestingly, both studies demonstrate that the TV of the index lesion was underestimated by MRI (average underestimation 5.9% in Baco et al. without utility of a shrinkage factor and 30% in Rud et al. with a shrinkage factor of 15%) (15,80). Delongchamps et al. analyzed a cohort of 125 consecutive patients, who underwent mpMRI and both, TB and SB and consecutively RP for localized PC (16). MpMRI missed 10% of significant tumor foci on a per-lesion basis but none of the significant PC on a per-patient basis (16). MRI/TRUS-fusion guided TB missed 6% of their targets, resulting in an underdetection of 4% of significant PC (16). Their results suggest that TB alone performed in patients with a suspicious mpMRI would not leave patients undiagnosed with aggressive tumors (16). However, SB in patients with normal mpMRI but increased PSA should not be omitted (16).

MRI in patients with low-risk cancer—utility among men undergoing AS

Accurate risk stratification of patients undergoing AS versus active treatment is crucial for a sound AS program with high patient safety and to reduce potential morbidities associated with radical treatment (88). The most criticized part of AS is its dependence on the initial biopsy quality, since a high number of PC are upgraded in GS after RP (39,89). This cumulates in rather low treatment-free survival rates, although a recently published large cohort study, including 819 patients harboring low-risk PC, has demonstrated excellent results in 10-year (98.1%) and 15-year (94.3%) PC-specific survival.

Accurate and safe stratification means to correctly rule in low-risk disease on the one hand, and to rule out significant PC on the other hand. With regards to AS candidacy, Vargas et al. demonstrated that mpMRI can predict upstaging in re-biopsies of AS patients in up to 98% (90,91). Similarly, the utility of MRI/transrectal ultrasound (TRUS)-fusion biopsies in AS cohorts has been demonstrated with encouraging results. Hu et al. have shown an upgrading in PS, core involvement and TV of 36% compared to 12-core-TRUS-biopsy (92). Best detection accuracy was demonstrated for the combination of TB and SB, as TB alone led to underdetection of 10% of significant PC (92).

A recently published systematic review focused on mpMRI in AS (93). Schoots et al. found an overall reclassification rate of 33% according to PRIAS criteria when TB are used after initial SB (93). In AS follow-up, mpMRI using PIRADS scoring has the potential to rule out significant PC. Mullins et al., Vargas et al. and Da Rosa et al. showed a NPV of above 90% for a pristine MRI to rule out significant PC (90,94,95).

Thus, Schoots et al. conclude that MRI can detect clinically significant disease in one third to half of men at the start of surveillance and in the follow-up course (93). However, at the moment no robust data are available to support the use of MRI in place of repeat biopsy to detect progression over time (93).

The role of MRI in risk stratification and prediction of ECE and RP outcome

MpMRI has demonstrated excellent accuracy in index lesion detection, compared to RP specimens described by recent publications. However, risk group stratification for localized PC, as defined by NCCN criteria incorporates serum PSA-level, the GS of biopsy specimen and the clinical T-stage based on digital rectal examination (DRE) and lacks formal mpMRI incorporation (96).

In the 2012 ESUR guidelines a scoring system for extracapsular disease was published, including criteria regarding ECE, seminal vesicle infiltration (SV), adjacent and infiltration of distal sphincter and bladder neck (Table 3, Figure 5) (9).

Somford et al. validated the ESUR scoring system in a
Table 3  ESUR scoring of extraprostatic disease, according to ESUR prostate MR guidelines (9)

Figure 5  Figures are demonstrating the ESUR ECE-score on mpMRI (T2w Imaging) and histopathologic correlations for every level (9): (A) ESUR extra-capsular extension Score 1—Abutment; (B) ESUR extra-capsular extension Score 3—Irregularity; (C) ESUR extra-capsular extension Score 4—Neurovascular bundle thickening; (D) ESUR extra-capsular extension Score 4—Bulge, loss of capsule; (E) ESUR extra-capsular extension Score 5—Measureable extra-capsular disease. ESUR, the European Society of Urogenital Radiology; ECE, extracapsular extension.

cohort of 183 patients and found a NPV of 87.7% for ECE in patients with low-risk PC and a PPV for ECE in high-risk patients of 88.8% (28). This was slightly higher than an already excellent PPV in the studies of Cornud et al and Rud et al. (97,98). Marcus et al. investigated the impact of preoperative MRI on NCCN risk group classification in a cohort of 71 patients and found that 16.9% of patients were upstaged by MRI, mostly (83.3% of these subgroups) from intermediate- to high-risk (29). Additionally, the treatment regime was changed in 8.5% due to presurgical MRI (29). McClure et al. focused on differences between the initial surgical plan, according to D’Amico risk stratification, and the performed RP with knowledge of the presurgical MRI (99). They found a change in the initial surgical plan in 27% of patients, analyzing a cohort of 104 consecutive men (99). In their study, the surgical plan was changed to a nerve-sparing
technique in 61% and to a non-nerve-sparing in 39% (99). Wang et al. and Sala et al. from Memorial-Sloan-Kettering Cancer Center developed a score for ECE and seminal vesicle invasion that is analogous to the PIRADS score published by the ESUR (100,101). They found an AUC of 0.76 for MRI to predict seminal vesicle invasion. When the MRI score was compared to a Kattan nomogram, the combination of both significantly increased the AUC (AUC 0.86 versus AUC 0.80 for Kattan nomogram, P<0.05) (100). Sala et al. reported an AUC of 0.87 for prediction of ECE in a cohort of 45 patients how underwent salvage RP (101).

In contrast to clinical parameters like NCCN criteria, prostate MRI offers localized staging and allows the surgeon to sculpt the extent of PC and possible ECE (102). Another decision-making tool is maximum capsule contact length on MRI. Baco et al. analyzed the predictive value of MRI-determined tumor contact length to the capsule and found a correlation between ECE and tumor contact length of r=0.839 (P<0.001) using Spearman’s regression (103). Based on ROC curve analysis, the best threshold of MRI determined tumor contact length was 20 mm (103).

In conclusion, MR imaging can potentially improve the accuracy of the surgeon’s decision to resect or preserve the neurovascular bundle in patients undergoing RP (102).

Conclusions

MpMRI represents a potential tool to overcome limitations of conventional TRUS-biopsy. The established PIRADS scores make mpMRI generalizable and reproducible. Compared to the gold-standard of RP, MRI detects app. 90% of significant index lesions correctly, but TV is currently underestimated. Several techniques of TB are available and the optimal method has not yet been established. The encouraging results of in-bore TB and MRI/TRUS-fusion guided biopsies may outperform VE. TB detect significantly more significant PC compared to SB and are non-inferior compared to TPMB as reference test. However, as long as TB miss around 5-15% of significant PC (according to different definitions of significance), SB should not be omitted, especially in patients without previous biopsy. Among patients under AS, mpMRI helps to confirm AS eligibility, by correct prediction of upstaging in re-biopsies of AS patients and by accurately ruling-out significant PC. The future role of mpMRI in the presurgical setting of RP is emerging, as mpMRI can help to change the initial surgical plan, according to clinical decision making, in up to 30% of cases. Before wide incorporation of mpMRI, further comparative studies, including randomized multicenter studies, and evaluation of cost-effectiveness are necessary, but potential cost-saving approaches like biparametric MRI are in the starting gates. Additionally the role of molecular imaging, e.g., PSMA-PET-CT/MRI, might provide ancillary information on tumor characterization and PC aggressiveness, and its role will be depicted in further publications (104,105).
