Background: In China, the incidence of benign prostatic hyperplasia (BPH) is rising with the average lifespan of men. Transurethral resection of the prostate (TURP) is recognized as the gold standard for surgical treatment of BPH. Continuous bladder irrigation (CBI) is often required after operation. The irrigation rate is often manually adjusted based on the color of the drainage fluid, but it is difficult to know how much to adjust it based on color. To better adjust the irrigation rate and reduce related complications, we developed and evaluated a post-TURP CBI rate adjustment card.

Methods: A total of 103 BPH patients who underwent post-TURP CBI at our hospital between April and July 2020 were enrolled in this study and were assigned to the control group (n=49) or the experimental group (n=54) according to the different hospital areas. In the control group, the CBI rate was adjusted based on the clinical evaluation of the color of the drainage fluid; in the experimental group, the CBI rate was adjusted based on the color of drainage fluid evaluated with our homemade post-TURP CBI rate adjustment card.

Results: The incidence of bladder spasm, the incidence of clot-related catheter blockage, the volume of irrigation solution used, and the irrigation time were significantly lower or shorter in the experimental group than in the control group. The patient satisfaction score was significantly higher in the experimental group (P<0.05).

Conclusions: For BPH patients receiving post-TURP CBI, the homemade post-TURP CBI rate adjustment card can provide objective data for clinical care, reduce postoperative complications, and improve patient satisfaction. Therefore, it should be more widely used in clinical practice.

standard for surgical treatment of BPH (4); its advantages include wide indications, small incision, and good outcomes (5). The most common complications in the early post-TURP stage are postoperative bleeding and bladder spasm (6,7). Clot-related catheter blockage in the early postoperative stage may induce bladder spasm, which in turn aggravates bleeding and blockage. To prevent the vicious cycle of bleeding, catheter blockage, and bladder spasm (8), continuous bladder irrigation (CBI) is routinely performed after operation (9). However, an improper CBI rate is another cause of bladder spasm and bleeding, and the CBI rate can be properly adjusted based on the color of the drainage fluid (10). Most nurses manually adjust the irrigation rate based on their subjective evaluation of the color of the drainage fluid, which may affect clinical outcomes depending on each nurse’s clinical experience and skill level (11). It is difficult to quantify how much to adjust the post-TURP CBI rate based on the color of drainage fluid (12). In this study, we developed and evaluated the effect of a post-TURP CBI rate adjustment card in BPH patients undergoing post-TURP CBI in order to provide a scientific basis for objectively evaluating the color of drainage fluid and precisely adjusting the CBI rate. We present the following article in accordance with the TREND reporting checklist (available at http://dx.doi.org/10.21037/tau-20-1288).

Methods

General information

BPH patients who received post-TURP CBI at our hospital between April and July 2020 were enrolled in this study. All procedures performed in this study involving human participants were in accordance with the Declaration of Helsinki (as revised in 2013). Inclusion criteria were as follows: (I) 60 to 80 years of age; (II) BPH confirmed by ultrasound B, urodynamics, and serum prostate-specific antigen; (III) normal coagulation before operation; and (IV) elective TURP. Exclusion criteria were as follows: (I) prostate cancer, neurogenic bladder, bladder neck sclerosis, or other urethral conditions; (II) other severe organic disorders; and (III) use of an analgesic pump after operation. Each patient signed the informed consent before the study, which was approved by Medical Ethics Committee, First Affiliated Hospital of Soochow University (approval No. (2020) EC 017). A total of 103 eligible patients were enrolled in this study and were assigned to the control group (n=49) or the experimental group (n=54) according to the different hospital areas. No significant between-group difference was observed in sex, age, or underlying diseases (P>0.05) (Table 1). All procedures performed in this study involving human participants were in accordance with the Declaration of Helsinki (as revised in 2013).

Study methods

Routine post-TURP CBI

After TURP, all the patients received CBI through an indwelling three-lumen catheter. The bladder irrigation solution was 3 L per bag, which was placed at 60 cm above the bladder for irrigation at room temperature (25 °C). During CBI, the patient was closely monitored for catheter patency. In case of any blockage due to clots, the catheter was gently squeezed and repositioned, or a syringe was used to flush the catheter repeatedly with sterile saline if needed until the blockage was cleared. Urine output, the input of irrigation solution, and liquid output were recorded (urine output = liquid output − the input of irrigation solution); and the color and property of drainage were observed. A gauze was secured at the urethral opening for light traction for 12 h. The patients were instructed to avoid unnecessary changes in position for 24 h after operation; meanwhile, they received passive movement and proper care to prevent pressure sores or lower limb thrombosis. Mental counseling was also provided as needed.

Control group

In the control group, the irrigation rate was adjusted according to the standard of care. Specifically, the nurse evaluated the color of the CBI drainage fluid under bright light and increased the rate if the color was dark, and vice versa (10).

Experimental group

In the experimental group, the irrigation rate was adjusted with the post-TURP CBI rate adjustment card. (I) The card was made of plastic, 15 cm × 10 cm, with two parts: color grade and irrigation rate (Figure 1). Our pilot study demonstrated the consistency of the color grade, which included six colors commonly seen in clinical practice. We applied for a patent for the card in April 2020. The quantitative relationship between the irrigation rate and color grade was validated through clinical experience, expert consultation, and preliminary tests.

Figure 1 Post-TURP CBI rate adjustment card. TURP, transurethral resection of the prostate; CBI, continuous bladder irrigation.
(II) The entire department received relevant training to learn how to use the rate adjustment card. Before surgery, the responsible nurse educated patients and their families on the color of CBI drainage fluid. It is ok if the color is No. 2 or below, but medical attention is required if the color is No. 3 to No. 6. This education promoted understanding and cooperation while reducing unnecessary anxiety among patients and families.

(III) The rate adjustment card was compared with CBI drainage under bright light to determine the color grade of the drainage. This comparison was the basis for the rate adjustment according to the rate indicated on the card. In the case of between-grade colors, the higher grade was used (Figures 2, 3).

Outcome measures

Incidence of bladder spasm
Bladder spasm was evaluated with the bladder spasm symptom scale, in which the content validity ratio (CVR) was greater than 0.6 for each item. Scoring criteria were as follows: 1 point for postoperative urination urgency, defecation urgency, pain in the bladder area, or catheter blockage due to high pressure in the bladder; 2 points for unbearable pain in the bladder area, urine leakage around the catheter, or backflow of irrigation solution. The highest score is 10, and bladder spasm is diagnosed if the score is 4 or more (13).

\[
\text{Incidence of bladder spasm} = \frac{\text{the number of bladder spasm cases (n)}}{\text{total number of patients (N)}} \times 100\%.
\]

Bleeding
Based on a literature review (10) and our clinical experience, we evaluated bleeding with the incidence of postoperative clot-related catheter blockage, the volume of irrigation solution used, and irrigation time.

(I) Incidence of clot-related catheter blockage: Significant bleeding at the incision surface may promote clotting in the bladder and subsequent catheter blockage. Therefore, clot-related catheter blockage is an indirect indicator of postoperative bleeding. When the patient complained of a “full” bladder with CBI blockage, the condition was considered clot-related catheter blockage if it could be cleared by squeezing the catheter or by negative suction with a syringe, followed by the observation of clots in the catheter. Incidence of clot-related catheter blockage = the number of clot-related blockage cases (n)/total number of patients (N) ×

![Figure 2 Post-TURP CBI. TURP, transurethral resection of the prostate; CBI, continuous bladder irrigation.](image)

![Figure 3 Color comparison for CBI drainage. CBI, continuous bladder irrigation.](image)
(II) Volume of irrigation solution used: CBI is performed to dilute and drain blood from the bladder. More irrigation solution should be used if the drainage fluid is red. Therefore, the volume of irrigation solution used is an indirect indicator of postoperative bleeding. It was defined as the volume of irrigation solution used (3 L/bag) from the start of CBI to the end of CBI.

(III) Irrigation time: Clear drainage fluid from CBI indicates that the bleeding at the incision surface has stopped, and CBI may be discontinued. Therefore, irrigation time is a direct indicator of postoperative bleeding time. Irrigation time was defined as the time from the start of CBI to the end of CBI.

Patient satisfaction
Patient satisfaction was evaluated with the 19-item Newcastle Satisfaction with Nursing Scale (NSNS) (14). The Cronbach’s α of NSNS is 0.96, and the scale can be used for care-specific evaluation of patient satisfaction. The scale is a 5-point scale, where 1 indicates “very dissatisfied” and 5 indicates “very satisfied,” and the total possible score is 19 to 95. A higher score indicates a higher level of patient satisfaction.

Statistical analysis
SPSS 23.0 was used for data analysis. Normally distributed measurement data are expressed as mean ± standard deviation and were analyzed with the t-test. Nonnormally distributed measurement data are expressed as median with interquartile range and were analyzed with Wilcoxon’s rank sum test. Count data are expressed as percentage and rate and were analyzed with the chi-squared test. P<0.05 was considered statistically significant.

Results

Incidence of bladder spasm and bleeding indicators

The incidence of bladder spasm, the incidence of clot-related catheter blockage, the volume of irrigation solution used, and irrigation time were significantly lower or shorter in the experimental group than in the control group (P<0.05) (Table 2).

Patient satisfaction

Patient satisfaction score was significantly higher in the experimental group than in the control group (P<0.05) (Table 3).

Discussion

Using the rate adjustment card to effectively reduce the incidence of bladder spasm and improve postoperative bleeding

During CBI, irrigation solution fills the bladder while blood, irrigation solution, and urine were drained from the
bladder via a three-lumen catheter. Improper CBI may cause bladder irritation and induce bladder spasm and bleeding (8), which are quite common. According to the literature (10), the incidence of bladder spasm is 15.79% to 55.71%, and the incidence of clot-related catheter blockage is 10.53% to 30.00%. In addition to pain, bladder spasm causes catheter blockage and secondary bleeding at the incision surface, delays postoperative recovery, prolongs hospitalization, and increases medical costs. Bleeding has the same adverse effects. In this study, the incidence of bladder spasm was 28.57% and of clot-related catheter blockage was 22.45% in the control group, which were in line with the literature. High irrigation rates cause mechanical damage to the bladder wall, which increases bladder sensitivity, induces bladder spasm, and even aggravates bleeding. Low irrigation rates can be ineffective and thus lead to inefficient blood drainage from the bladder, which may lead to catheter blockage and then bladder spasm and bleeding. Therefore, proper postoperative irrigation rate helps reduce bladder spasm and bleeding.

Ding et al. (10) developed a wireless sensor-based automated rate adjustment device for post-TURP CBI. In the device, a computer system was used to evaluate the color of drainage fluid and automatically adjust the CBI rate. Their results showed that the device reduced bladder spasm and clot-related catheter blockage relative to the conventional manual method. However, the researchers did not quantify how much to adjust the CBI rate based on the color of the drainage fluid. Moreover, the high cost of the device limited its use. In this study, we quantified the adjustment of the post-TURP CBI rate with a homemade post-TURP CBI rate adjustment card. The results showed that the card reduced the incidence of bladder spasm to 11.11%, which was significantly lower than that in the control group (28.57%). Bleeding indicators were also significantly improved in the experimental group (incidence of clot-related catheter blockage: 7.41% vs. 22.45%; volume of irrigation solution used: 50.66±37.13 vs. 101.55±52.63 L; irrigation time: 46.58±20.01 vs. 63.75±29.65 h). These data indicate that the rate adjustment card reduces postoperative bleeding. Conventional irrigation rates are approximately 120 gtt/min. This study however shows that that rate is too slow and is ineffective in patients with significant bleeding, as it may cause clot-related catheter blockage and subsequent bladder spasm and bleeding and will increase the volume of irrigation solution used and the irrigation time. According to the standard of care, the irrigation rate should be increased if the color of the drainage fluid is dark and decreased if it is light. The color of drainage fluid is a real-time indicator of bleeding, but the evaluation process is different from individual to individual (15,16). This variation may lead to improper adjustment of the irrigation rate, an important cause of bladder spasm and bleeding. In this study, nurses used the rate adjustment card to evaluate the color of drainage fluid and adjust the irrigation rate accordingly in the experimental group, which effectively reduced bladder spasm and postoperative bleeding.

**Higher level of patient satisfaction with the rate adjustment card**

Patient satisfaction evaluation is a patient-centered evaluation of inpatient experience (17,18). In this study, the homemade post-TURP CBI rate adjustment card significantly improved patient satisfaction. This was likely because the card improved the overall quality of care. Moreover, perioperative patient education on CBI and the use of the rate adjustment card helped answer the patients’ and families’ questions and reduce their anxiety about the color of drainage fluid and irrigation rate adjustments (14). Furthermore, the use of the rate adjustment card standardized the procedures of post-TURP CBI and provided a scientific basis for color evaluation and rate adjustment, which facilitated communication between physicians, nurses, and patients, thereby improving patient satisfaction.

**Conclusions**

In this study, we evaluated the use of a post-TURP CBI rate adjustment card in patients receiving post-TURP CBI. Its use standardized the procedures of CBI, reduced postoperative CBI-related complications such as bladder spasm and postoperative bleeding, and improved the quality of care. The rate adjustment card is safe, effective, objective, and inexpensive, so it should be used more widely in clinical practice. In the interest of time, this study only enrolled patients receiving post-TURP CBI. Further research is needed to investigate the use of the rate adjustment card in patients receiving CBI for other conditions.
